ABSTRACT
Robots designed to interact with people in collaborative or social scenarios must move in ways that are consistent with the robot’s task and communication goals. However, combining these goals in a naïve manner can result in mutually exclusive solutions, or infeasible or problematic states and actions. In this paper, we present Lively, a framework which supports configurable, real-time, task-based and communicative or socially-expressive motion for collaborative and social robotics across multiple levels of programmatic accessibility. Lively supports a wide range of control methods (i.e., position, orientation, and joint-space goals), and balances them with complex procedural behaviors for natural, lifelike motion that are effective in collaborative and social contexts. We discuss the design of three levels of programmatic accessibility of Lively, including a graphical user interface for visual design called LivelyStudio, the core library Lively for full access to its capabilities for developers, and an extensible architecture for greater customizability and capability.

CCS CONCEPTS
- Human-centered computing → Open source software.

KEYWORDS
Robot motion; robot control; Perlin noise; lifelikeness

ACM Reference Format:

1 INTRODUCTION
As robots increasingly work in human environments, they will need to execute a wide range of highly configurable behaviors while communicating effectively with their users. A worker collaborating with a robotic arm may have preferences for how the robot positions itself when they are nearby [25]. A collaborative robot assisting a person unloading the dishwasher might use slight movements of its gripper to communicate that it is ready to pick up or receive...
items [47]. A social robot may display idle motion with its body to indicate that it is active and lifelike [29]. When conversing, a robot may look away to signal that it is thinking [1]. Prior research in human-robot interaction has found such “lifelike” motions to improve perceptions of the robot [43, 48]. Thus, lifelike motion or configuration of a robot’s links and joints are key design elements for robots utilized in human environments. Successful execution of combined tasks and social actions requires balancing these types of goals with practical concerns, such as avoiding collisions and maintaining smooth motion. In this paper, we explore how Lively can support the generation of lifelike but feasible task motions for collaborative and social robots.

Since physical task-based activities are frequently spatially rooted in the workspace, robot control requires converting these Cartesian goals into joint-space instructions. For example, the ability of a robot’s arm to deliver an object to a collaborator depends on its ability to first reach the position of the object, and then travel to the person’s outstretched hand. Similarly, a social robot may point in a certain direction using referential gestures by changing the position and orientation of its hand or gaze. This conversion is commonly achieved with an approach known as Inverse Kinematics (IK). Conventional IK approaches structure this conversion as a search in joint-space constrained by the position and orientation of the robot’s gripper. This approach encourages solutions exhibiting desired position and orientation goals on the gripper, but cannot guarantee finding a solution in all cases.

To communicate certain attitudes or states with physical motion, such as the human-robot interaction scenarios discussed above, the entire kinematic chain may be required, so simply considering the position and orientation of the gripper is insufficient.

Combining these social and task-based goals into functional robot motion requires not only knowledge of how motion is interpreted but also the technical ability to translate those qualities onto robot platforms. While robotics application developers may possess skills in both areas, domain experts may not have the same level of technical ability to bring their vision to fruition. An interface that is intuitive to both roboticians and other experts, such as animators, artists, or designers, can bridge this divide. Additionally, novel approaches to designing and implementing robot motion may be needed as robot capabilities evolve. Therefore, a design system with the flexibility to grow with these new approaches is required.

We present a new motion specification and generation framework, called Lively, that combines task-based and social goals while maintaining kinematic stability in real time (Figure 1). The framework leverages Perlin noise [30, 32] and integrates an existing per-instant pose optimization tool called RelaxedIK [37] to achieve both primary and secondary motion goals in real-time. To support robot-application designers and developers, we developed three levels that expose the capabilities of Lively to users with different needs and levels of expertise. At the first level, LivelyStudio provides nonexpert users with an accessible, interactive, visual interface to design primary and secondary motions and control modalities used with the robot. At the second level, we present a development- and execution-focused framework, and at the final level, we provide an architecture that supports extendability and customizability.

The contributions of our work are summarized as follows:

- A visual interface called LivelyStudio that allows designers to interactively construct state-based robot programs.
- An open-source robot-agnostic library that can be used by developers to specify real-time robot behavior that combines goal-oriented joint-space or Cartesian control with motion quality attributes in a feasible manner.
- A modular software architecture that supports straightforward augmentation and contribution for custom control.

In the remainder of the paper, we review previous approaches to this problem, contrasting them with Lively. We discuss the implementation of Lively and outline its cases for use along three different levels of programmatic accessibility, including the design of a tool called LivelyStudio, iteratively designed with a formative evaluation with roboticists and animators.

2 BACKGROUND

In this section, we review related work on expressive and functional motion including lifelike motion, inverse kinematics, and the operationalization of each.

2.1 Lifelike Motion

Whereas primary motion is an intentionally performed behavior, such as the process of handing a letter to a friend, standing in place, or looking to the right, secondary motion is defined as activity resulting from that primary motion [23]. Secondary motion covers a wide range, such as the rippling or creasing of one’s shirt as the arm is outstretched, the idle shifting of posture while standing, or slight movements of the pupils.

Secondary motion is known to be highly important to how humans interpret animated or robotic characters. In their paper, Heider and Simmel animated a set of shapes to perform choreographed motions, such as following one another and moving into boxes while exhibiting additional subtle affine and rotational movements [20]. Most participants viewing the animation described the behavior of the simple shapes in human or anthropomorphic terms. Similarly, work with puppets has informed our understanding of how small motions and characteristics can influence viewers [12, 14]. The effectiveness of secondary motion motivated its inclusion in the principles of 3D animation by Lasseter [26].

Animation utilizes many principles for secondary motion and lifelike behavior, initially requiring hand-drawn or hand-animated specification of behaviors. However, a growing number of methods make this process less demanding. Witkin et al. proposed a method to warp a keyframe animation to match new spatio-temporal constraints by systematically mapping underlying motion curves [51]. This allows an animator to adjust a character’s posture from happy to sad throughout an animation using only a sparse set of inputs instead of enumerating keyframes. Gleicher presented a method that maps motion from one articulated figure to another, even if they have vastly different scales or geometries [17]. The method uses non-linear constrained optimization to minimally displace an input motion (e.g., motion capture data) to match the specifications of the new articulated figure. Additionally, motion has been added to computer generated characters using Principal Components Analysis.
with secondary motion through a 3D intermediate process [22]. However, these solutions all represent post-hoc methods of adjusting input motions, and are allowed certain freedoms given their virtual, non-rigid context.

Considerable work has also focused on effective ways of augmenting agents and characters with secondary motion in a generative manner. The most common method to do this was created by Ken Perlin [30, 32]. Originally designed for texture generation, Perlin noise was quickly adopted for motion as a way of creating personality in animated characters [6, 31]. Perlin noise is particularly well-suited for this domain, being a non-repeating, but smoothly changing generative method. Furthermore, by modifying the speed at which the input value (usually a function of time) changes, animators can predictably control the characteristics of the noise function. By using smooth noise, such as Perlin noise, as a function of time, offsets from static or dynamic configurations (i.e., character joints) can be calculated, thus augmenting these characters with subtle motion. This process was extended by Improv, which featured a method for incorporating smooth noise into animated characters’ behaviors [33]. Studies in robotics have shown smooth noise to improve a variety of outcomes in robotics, including likeability and presence [8, 48]. Many commercially-available collaborative and social robots do not have fully articulated faces with which to communicate social-emotional states, so it is particularly important that there be alternative ways for modeling them.

Specific characteristics of motion, such as “jerkiness” or “velocity,” have been outlined as important for the recognition of certain emotional states in humanoids robots [3, 4]. When viewed by individuals, faster speed in robots was interpreted as greater excitement [22]. viduals, faster speed in robots was interpreted as greater excitement in a virtual, non-rigid context.

Results in unstable posture, and even falls.

Joint-space can result in problematic configurations or collisions, noise causes varying speed or jerkiness in Cartesian space. Many features, such as speed or jerkiness, may be obscured if joint-based features, such as speed or jerkiness, may be obscured if joint-based noise causes varying speed or jerkiness in Cartesian space.

Similarly, the addition of smooth noise for secondary motion in joint-space can result in problematic configurations or collisions, even if joint limits are respected. For humanoid or bipedal robots, simply adding offsets to individual joints on the lower limbs quickly results in unstable posture, and even falls.

### 2.2 Solutions to Lifelike Motion in Robotics

One solution to these challenges is to simply pre-record or define keyframes for specific motions and interpolate between them as needed. This approach has been employed in prior research [48] and in proprietary software (e.g., Softbank Robotics’ NaoQi Autonomous Life [41]). As an alternative to manually generating activities, Geppetto utilized a user interface to enumerate and visualize possibilities for expressive gestures with the goal of allowing more productive exploration of the potential behavior set [11]. For bipedal robots, motion on limbs presents an additional challenge due to instability caused by uncoordinated joint movements. As a result, motion is typically either disabled from the waist down, entirely pre-defined, or the issue is avoided by adopting a sitting position and focusing activity on the upper body [3, 4]. While sufficient for short interactions, pre-scripting these behaviors can have a number of issues. First, without enough keyframes, the behavior can quickly become repetitive, which breaks the illusion of autonomy [13]. Second, when combining activities, conflicts between joints and kinematics might arise. This makes interleaving existing motion with novel, real-time instructions difficult. For example, an early approach attempted to resolve these conflicts between activities and motions through a hierarchical model [45]. While effective at interleaving the behaviors with motion, the system was not fast enough to run in real-time. These cases illustrate the limitations of previous efforts to balance lifelike motion with task-goals.

### 2.3 Inverse Kinematics

In contrast to specifying the gripper pose indirectly through the setting of joint angles, Inverse Kinematics (IK) solvers attempt to directly specify the gripper pose, and solve for the joint configuration that satisfies that pose. IK solvers, while more easily interpretable in Cartesian space than joint-space methods, can encounter issues such as kinematic singularities. These joint-space issues occur when the robot loses the ability to instantaneously move its gripper in some translational or rotational dimension, because (1) not all poses in the robot’s area can be reached through a combination of joint states, and (2) a movement in Cartesian space may not be possible as a smooth interpolation of joint-space values.

A method that utilizes an IK solver is ERIK, which uses a pass-based approach to integrate joint movements with end-effector goals [40]. RelaxedIK is another IK solver with a different approach. Using an optimization-based method, RelaxedIK places importance on both accuracy of the motion (e.g., matching the pose of the gripper), as well as the feasibility of motion (e.g., avoiding self-collisions or kinematic singularities) [37]. It is generalizable such that additional objectives can be added, e.g., handling dual-robot systems where one arm controls a camera, optimizing the location and orientation of the camera such that a remote user has a clear view of the task being performed by the other robot arm [38].

### 3 IMPLEMENTATION

Lively inherits its philosophy from RelaxedIK [37] by framing the goal of the joint-space calculation as an objective, but generalizing its implementation across a greater set of objective types and attributes of the robot’s state. Furthermore, while RelaxedIK assumed a position and rotation goal on the gripper of each robot arm, and a
were supported through modes, there was no clear relationship to work, while maintaining its accessibility. This is done by using a à la carte (P3). “More generally, how specific goals could be combined with goals (task-based instructions). While states are merged for clarity, and weights are inferred from their relative ordering within states and through usage of priority groups. Designers can specify arbitrary Universal Robot Description Files (URDFs), but visualization of meshes is limited to a discrete set that could be expanded in the future.

Figure 2: An early version of LivelyStudio that received feedback from animators and roboticists, which led to a re-designed 3D environment, more explicit state-based design process (states as graph nodes), and bundling of behavior attributes with specific goals and weights.

set of joint smoothness objectives, Lively makes fewer assumptions with its à la carte approach, giving the programmer greater ability to compose these goals in creative ways for behavior generation.

To explore the capabilities of the system, we will consider three main levels of possible interaction with the system: the Design Level, the Development Level, and the Extension Level.

3.1 Design Level

The outermost interaction level is the Designer Level, and is the least technical way to explore and utilize the system. We designed LivelyStudio as a method inspired by conversations with a set of experts across the fields of animation and robotics. It is meant to support and illustrate many of the capabilities of the Lively framework, while maintaining its accessibility. This is done by using a state-based approach, wherein users can compose combinations of social, task-based, or functional behaviors, called Behavior Properties, and specify how transitions may occur between these states.

3.1.1 Design Iteration. Our current version of LivelyStudio builds upon previous iterations through a small formative evaluation with four professional roboticists and animators involving a mixture of system overview, think aloud, and semi-structured interview, lasting 60 to 90 minutes. The initial design, shown in Figure 2, featured a simulator and configuration window, where users could independently curate a set of Behavior Properties, a set of states (called modes), and goals (task-based instructions). While states were supported through modes, there was no clear relationship between them, and animators in particular had difficulty translating their keyframe-focused experience to this design: “It’s hard to see how poses would be created so separate from the animation (P3).” More generally, how specific goals could be combined with the Behavior Properties was unclear. Additionally, certain interface elements, such as the standard 3D viewer did not have the affordances desired by animators, or had minor usability issues. This feedback was used to create a more effective and intuitive version of LivelyStudio for users of varied backgrounds and levels of experience through a more explicitly state-based configuration process, and use of a new custom 3D viewer and updated components.

3.1.2 LivelyStudio Interface. The results of our formative evaluation suggested that a state-based visual programming environment that allows users to develop series of states similar to keyframing would be the most intuitive approach to the design. The state-based approach shares similarities with many other programming environments [9, 16, 34, 35], which may be familiar to roboticists, but also enables an intuitive design approach for users who are less familiar with typical programming environments like animators, digital artists, or other types of designers. LivelyStudio’s programming environment contains three primary parts: (1) a selection of state and behavior property nodes, (2) a state-based programming window, and (3) a robot scene. By defining states, and adding Behavior Properties, designers can define how a robot will move, or the position it should take in each (Figure 3). Improving on the early version of LivelyStudio, specific goals and Behavior Properties are merged for clarity, and weights are inferred from their relative ordering within states and through usage of priority groups. Designers can specify arbitrary Universal Robot Description Files (URDFs), but visualization of meshes is limited to a discrete set that could be expanded in the future.

3.1.3 Behavior Properties. LivelyStudio allows for a wide range of robot Behavior Properties with which users program robot motion. These 24 properties, which serve as building blocks for defining the behavior and motion of the robot, fit into six categories:

- **Basic behavior properties** revolve around the fluidity of robot motion by limiting rapid changes and considering possible collisions between the links of the robot.
- **Bounding behavior properties** limit the space within which joints can assume angles and links can move or be oriented.
- **Matching behavior properties** specify exact positions and orientations of links or angles of joints.
- **Mirroring behavior properties** allow users to mirror the current state of a link’s position or orientation in a different link, or the current angle of one joint in another.
- **Liveliness behavior properties** allow the addition of smooth, coordinated motion to joint angles or link poses.
- **Force behavior properties** simulate the effects of physical forces acting upon the robot.

The function of each Behavior Property is visualized in Figure 4.

3.1.4 States and Transitions. The state-based programming window starts with a power-on (i.e., initial) state, and a power-off (i.e., final) state. Users can add additional state nodes to their program and populate them with Behavior Properties. For example, one state may contain a property that sets the gripper of a robot arm in a pick-up area, while another state sets the gripper position to be near a drop-off area. Once a series of states is created, the user can define how the power-on, power-off, and custom states are connected by dragging transitions from one state to another. These connections can also be given timers, which act as triggers to automatically begin a transition from one node to the next. In this way, a state can function both conventionally, defining a set of characteristics the robot will exhibit for an unspecified amount of time, but also as a single keyframe in a timed series. States can have any number of both timed and nominal transitions (simulating event triggers, e.g., a person approaches), and the program will transition states given the first simulated event triggered or timer that expires, whichever occurs first. Of note, while this does simulate how the robot could...
respond to events, LivelyStudio does not currently interface with physical robots, or listen to external events.

3.2 Develop Level

For robot programmers desiring greater control over the robot than that afforded by the previously described LivelyStudio interface, or looking to control a robot in a more conventional ROS-based approach by creating a control node that publishes joint values, the Development Level allows for direct control using Lively.

3.2.1 Design & Usage. Lively is written in Rust [27], and accessible as a crate, with bindings in both JavaScript through WebAssembly [18] and Python [42]. To use Lively, a Solver is imported and constructed with any valid URDF, persistent scene objects, objectives, and other solver settings. Execution of the solver method, which accepts the current goals, weights, time, and real-time collision data, returns a robot state that best satisfies those goals given the current weightings and previous robot state. This approach allows for Lively to be used in a variety of contexts, including ROS [36], web or simulation, and directly on hardware. Solve times with randomly arranged colliders are shown in Figure 5.

3.2.2 Objectives, Goals, & Weights. To achieve a high degree of customization and dynamic control, we introduce the concepts of objectives, goals, and weights. Whereas LivelyStudio abstracted away these features as Behavior Properties for the purpose of accessibility, the core framework allows for more direct control. The identities of the individual objectives match with the set of Behavior Properties enumerated in Figure 4, and goals are summarized in 1. Importantly, while Behavior Properties encoded the discrete goals (e.g., the position for Position Match, or the scalar for Joint Match) associated with each Behavior Property, and the weights are inferred by the ordered ranking within states, these are separated at the framework level. Thus, the previously mentioned position goal can be determined in real time through external means, such as sensing, and passed as an update within each iteration of the solver. Similarly, the developer in real time can adjust other goals, such as a position bounding ellipsoid (Position Bounding), joint values (Joint Match), or size (for Position Liveliness), and weights, allowing for prioritization of certain goals or the deactivation of others, based on the current development needs. Because objectives are organized by key, and atomic updates are possible for goals and weights, only the needed changes must to be included each round.

3.2.3 Objective Configuration. The complete set of objectives feature a wide range of configurable attributes, beyond simply their goals and weights. The simplest objectives focus on safe and smooth motion, corresponding to the set of Basic Behavior Properties, and do not accept additional parameters. Those corresponding to Matching, Bounding, and Gravity Behavior Properties are configured with the joint or link with which they are paired. Mirroring Behavior Properties, defining relationships between pairs of links and joints, accept a pair of each. Finally, Liveliness Behavior Properties feature an additional field, frequency. This value functions as a temporal scaling value that increases or decreases the rate of change in the Perlin noise generator functions for that objective. Combined with the goal values passed into liveliness objectives, developers can access a wide range of motion profiles. Importantly, because the formulation of the liveliness objectives is not dependent on having a concrete goal attached to the same link or joint, it is possible to add movement to otherwise uncontrolled parts of the robot.

3.2.4 Collision Avoidance. Lively implements the PROXIMA collision detection algorithm, which allows for time-efficient collision and proximity detection for robots [39]. The Collision Avoidance objective serves to utilize the data generated from this collision...
detection algorithm to prevent collisions. *Lively* employs a threefold approach to handling modeling collision objects. The first is input from the URDF during the initialization of the solver, which supports default shapes like boxes and cylinders as parts of the collision model when parsed. For cross-platform and web-based reasons, mesh-based colliders are ignored during URDF import. Additional colliders can be specified during `solve` initialization, including basic shapes and convex hulls, and can be attached to the world or any link in the robot. Finally, as an optional input to the `solve` method, developers can provide real-time updates to the collision model, adding, deleting, and moving colliders.

### 3.3 Extend Level

For robotics developers seeking to modify the behavior of the existing *Lively* objectives, or wanting to increase functionality by creating completely new objectives, *Lively* has a modular and configurable approach to supporting the Extension Level.

#### 3.3.1 State Model

As discussed, *RelaxedIK* utilizes an optimization approach, with the robot state $S_R$ being represented as a vector in the joint space $S_J$ of the robot internally. *Lively* takes a similar approach, but an additional six dimensions representing the transform of the root link are added to create the optimized vector $x$. However, this vector representation is not always the most natural way to evaluate the state, and to ease the computation each objective performs, this vector is converted into a more comprehensive state representation containing joint states, link transforms, and proximity information, described in Table 2. This state, as well as previous states, are provided in each call to objectives.

This formulation of the state allows for straightforward creation of additional objectives. It is also possible that additional features of state may be needed for the creation of certain new objectives. The *Robot Model* handles the generation of new robot states from the vector $x$. For example, if a force-based objective was desired, the robot model would have to be extended to output a state that provides the data the objective would have to operate on.

![Diagram of behavior properties](image)

**Figure 4:** *LivelyStudio*’s set of Behavior Properties that match Objective Functions within *Lively*. Note, Velocity Minimization, Acceleration, and Jerk Minimization come in both joint-based and robot root variants, and while usable separately, are included within the Smoothness macro property.

![Graph showing solve times by robot and environment complexity](image)

**Figure 5:** Solve times for the UR3e, Panda, and Pepper robots, with randomized locations of environmental colliders. Of note, speed is largely unaffected by shape count.

#### 3.3.2 Objective Formulation

Similar to robot state, each objective adheres to a well-defined convention that can be used to extend the capabilities of Lively, as shown in Table 3. As previously discussed, each objective is paired with a specific goal type (e.g., Position Bounding with Ellipse, and Position Liveliness with Size), and the goals are enumerated in Table 1. Additional goal types can also be added to support new objectives and functionality, as long as they have a predictable structure (e.g., a pointcloud goal could be an array of any length with structure \( \{ x : f64, y : f64, z : f64 \} \)).

### 4 CASE STUDIES

#### 4.1 Design Level

Users of a wide range of experience levels can engage with our system using LivelyStudio. Artists, character designers, and animators, who may not be familiar with traditional programming tools, may particularly benefit from LivelyStudio’s accessible user interface.

##### 4.1.1 Kiosk Robot

Suppose a user is creating a program for a social robot providing general assistance in a public area. Here, the robot may have states such as idle, greeting, or thinking. The user can begin by creating state nodes within the state editor. One such state could be labeled “Idle” to represent the idle status of the robot within the overall program. From here the user can begin adding Behavior Properties to the state. First, the user may apply the Position Liveliness property to the torso of Pepper as a visual indication that it is powered-on and functioning. Next, the user may add the Joint Liveliness property, and configure it to “Head Yaw” to make the robot’s head sway from left to right and signify that it is looking around for people to assist. Finally, the user can select the Smoothness Macro property to ensure that the robot’s motion remains smooth and natural, and the Collision Avoidance property to prevent collisions. The user may also create a “Greeting” state, which directs the robot’s gaze toward a nearby person. Once these states are generated, the user can create a connection between them and add a label to identify a triggering condition. The user may want Pepper to transition from the ‘Idle’ state to a ‘Greeting’ state when a person approaches. During this transition, Pepper can reduce head sway from the ‘Idle’ state, direct gaze toward the user in the ‘Greeting’ state, and maintain the liveliness motion included in both states. This process can be repeated with any number of states and complex transition patterns.

##### 4.1.2 Cobot Keyframing

In another example, a user may want to create a program for a robotic arm such as the Panda robot that functions as a series of states, similar to keyframing. The user can create an initial state, add the Position Match property, and configure a specific position for the gripper. The user can complete this process to define all waypoints for the gripper of the Panda robot as separate states. Given space constraints in the deployment environment, the user may also want to design their program to limit the space in which certain links will move. Thus, the user may apply the Position Bounding property to specific links so that the robot limits its spatial footprint while moving. Finally, the user may need the robot to interact with an object from a specific grasp point. Therefore, adding the Orientation Match property to the gripper enables it to manipulate an object from a reasonable angle. Once all the states are created, the user can create timed connections between states, such that transitions will occur automatically.

### 4.2 Develop Level

While all users may find use in LivelyStudio, those with substantive experience programming and planning robot motion will be able to leverage the capabilities of Lively directly. We consider two example use cases to explore how Lively may be used.

##### 4.2.1 Real-Time Robot Control

Using a UR3-e series robotic arm, a developer seeks to devise a system that, on button-press, scans the area using a camera attached to the last robot link, and finds any of a set of items. Any item it finds is picked up and placed in a nearby box. The developer creates a ROS-based setup with two nodes. One node receives a camera feed and transform data from the robot, while publishing all valid items and their transforms that it detects. A second, Lively-focused control node listens to this set of items, and publishes transforms of the robot to be consumed by the first node. The control node defines a Lively solver, configured with the robot description, and an additional camera collider that is attached to the last link. The solver is configured with Position Match and Orientation Match objectives on the final link, and a Position Liveliness objective on the forearm link. Finally, the set of objectives is completed with Smoothness, Joint Limits, and Collision Avoidance objectives. On button press, a preset collection of positions and orientations are sequentially passed to the corresponding objectives in the solve method, along with instructions to turn the liveliness
weight to zero. The resulting state is parsed and converted into TF messages, which are passed via a topic to the data parsing node. Upon calculation and communication of scene items to the control node, the node selects the first item to move, passing the position and orientation to the solver, followed by the goal position of the items, then repeating until no items remain. Once complete, the position and orientation goals are moved to a neutral pose, and the weights relaxed, while the liveliness objective weight is increased.

4.2.2 Browser-Based WOZ. A developer wants to create a ROS-based wizard-of-oz GUI interface that allows actions to be selected and executed on a robot in real time, but also want the robot to respond to potential collision objects in the environment and exhibit certain lifelike motions. The robot, Pepper, has two arms, wheels, and a head, and the developer already has an existing library of joint-based trajectories. However, they want to include additional liveliness in orientation space around the head and position liveliness (a swaying motion) on the torso. Objectives for each controlled joint are created, as well as some basic objectives. The developer’s GUI initializes a web-based version of the solver. A web-based ROS connection is formed to the robot, starting a subscription to sensor data, and a publisher that sends real-time joint instructions to the robot. Selecting an action updates the goals for each joint, and the set of all potential colliders that the robot gets from the sensors are updated each invocation of the solve method. Joint instructions from the result are passed to the robot after each solution is found. To accommodate all goals simultaneously, the system will attempt to reach the specified joint values, while adding in liveliness and avoiding collisions.

4.3 Extend Level

The current functionality of Lively and LivelyStudio address most user needs when programming robot motion. However, if additional functionality is desired, a developer could easily extend our system’s capabilities by defining new objectives and goals. We outline two examples of extensions that would be feasible within Lively.

4.3.1 Center of Mass Objective. Lively can be greatly extended through the development of additional objectives. Because the robot state already includes a vector representing the center-of-mass of the robot, it is straightforward to create a new objective, implementing the methods defined in Table 3, that operates on it, which could be useful in cases where the robot’s balance must be maintained, or as a way to center the robot near its base. The specified objective would accept a Translation goal, and use the default implementation of update. The call method would be implemented by calculating the distance between the goal value and the center-of-mass vector in the robot state, returning a cost that grows with distance. Finally, the objective is added to the set of Objectives. The resulting objective would attempt to produce poses that are centered as much as possible on the goal vector provided.

4.3.2 Perspective Noise. While the Position Match and Orientation Match objectives together are capable of creating a lifelike appearance, a developer may desire to create a lifelike behavior that exhibits positional and rotational motion around an offset focal point, as if inspecting the properties of an object located there. Doing so requires the addition of an new goal type, which would encode the focal length to maintain the position of the focus, and the amount of rotational/translational movement allowed. The objective’s call method would use these goals and a Perlin noise generator function to project the needed position and orientation in space to achieve the specified rotation around the focus at a given time and compute the radial and translational distance from those values, returning a cost value. The resulting objective would attempt to produce poses that adhered to this dynamic pattern as a function of time.

5 DISCUSSION

Simultaneous coordination of functional and expressive robot motions is necessary but challenging. While a naive approach may combine these types of motion, it may produce incompatible or undesirable results. In this paper, we presented a system that generates real-time, lifelike motion for collaborative and social robots, addressing key limitations of prior approaches at three levels of programmatic accessibility. At the most accessible level is LivelyStudio, a state-based visual programming and configuration environment that allows for exploration and design. Developers can utilize Lively directly in multiple programming and execution environments, in applications ranging from traditional keyframing-based to real-time control. Finally, we present an architecture for Lively that supports customizability and extendability.

5.1 Limitations & Future Work

The limitations of the work presented point toward future research and implementation opportunities. First, Lively currently takes a purely kinematic approach, but future extensions of Lively might apply dynamics to accommodate external or inertial effects on the robot’s motion as well as higher-level behavioral objectives for avoiding non-stationary objects and obstacles with base movement. Additionally, while supporting a high degree of configurability for liveliness-focused Behavior Properties, LivelyStudio could be made more effective through the use of programming by demonstration, in which designers could demonstrate an example of liveliness that they would like to see articulated with a physical robot connected to the system, which could be converted into corresponding Behavior Properties automatically. The growing field of soft robotics presents interesting and relevant challenges for effective control that should be explored with respect to Lively. Finally, we plan to holistically evaluate LivelyStudio and Lively with (1) a usability evaluation of LivelyStudio that focuses on usability, learnability, and effectiveness of the system in supporting motion design, and (2) a long-term community-based, qualitative evaluation of the develop and extend levels to better understand their usage in a rigorous but also ecologically-valid manner, considering community engagement and usage on public-facing hosting locations.

Taken together, Lively and LivelyStudio aim to assist and motivate future work in systems exhibiting both social and task-based motion as a platform for design, development, and extension.

6 ACKNOWLEDGEMENTS

This work was supported by the National Science Foundation (NSF) award IIS-1925043. We would like to thank Curt Henrichs and Yeping Wang for feedback and assistance, and the volunteer roboticians and animators for their feedback during development.
